Abstract

Possible explanation of the 64/20 redundancy of the triplet genetic code based on the assumption of quantum nature of genetic information is proposed.

The redundancy of the genetic code, where 64 possible nucleotide triplets code only 20 amino acids used as building blocks for all proteins, is well known. For a non-degenerate triplet code written in a four letter nucleotide alphabet (*ATCG*), the naive expectation of the possible coding repertoire is equal to the number of all sequences of r elements ($r = 3$, triplet) with each element taken from a set containing k elements ($k = 4$, number of bases):

$$A_r^k = k^r, \quad \text{or} \quad A_3^4 = 64. \quad (1)$$

In reality, only 20 amino acids are encoded, thus the code is degenerate because different triplets code the same amino acid. In each triplet the first two letters are more significant than the third one, but without full degeneracy: otherwise we would have only $4^2 = 16$ amino acids instead of 20. The endeavor of answering the question on the origin of 64/20 degeneracy utmost inevitably leads to the conclusion that on the early stages of evolution codon was functioning as a set of nucleotides, rather than an ordered sequence. If it is the case, the total number of functionally different combinations (functional keys) should be equal to the number of sets equivalent with respect to permutations of r elements with each element taken from a k -element set:

$$C_r^k = \frac{(k+r-1)!}{r!(k-1)!}, \quad \text{or} \quad C_3^4 = \frac{(4+3-1)!}{3!(4-1)!} = 20. \quad (2)$$

The coincidence between combinatoric rule (2) and the redundancy 64/20 was noted long ago by Gamov [1], who stressed it as a question to be answered in the future. Recently Patel [2], in relation to quantum computations, suggested that the choice of 20 amino acids is a result of optimization with respect to a quantum search algorithm, like that proposed by Grover[3]. The Grover's algorithm relates the number of objects N that can be distinguished by a number of yes/no queries, Q , according to

$$(2Q + 1) \sin^{-1}(1/\sqrt{N}) = \pi/2. \quad (3)$$

For $Q = 3$ the exact solution is $N = 20.2$. Thus, from the standpoint of quantum information theory, $N = 20$, being very close to 20.2, provides a quantum database search with minimal possible errors asking 3 questions only.

We would like to propose another interpretation of the genetic code redundancy 64/20. The formula (2) exactly coincides with the number of quantum states of a Bose gas of $r = 3$ particles with $k = 4$ possible quantum states, *i.e.* with the number of arrangements of r indistinguishable particles into k states.

The concept of an ideal Bose gas is an idealization used for adiabatically isolated systems of identical quantum particles. To some extent, we can suggest that this idealization works for the transcription and translation of genetic information. Taking into account that the typical codon size is about 0.5 nm, from the Heisenberg uncertainty principle

$$\Delta x \Delta p \approx \hbar, \quad (4)$$

we can easily infer that for the typical size of a nucleotide

$$\Delta p \sim \frac{1.05 \cdot 10^{-27} \text{erg} \cdot \text{sec}}{1.7 \cdot 10^{-8} \text{cm}} \approx 6.2 \cdot 10^{-20} \frac{\text{g} \cdot \text{cm}}{\text{sec}}.$$

For the typical mass of a hydrogen atom the energy associated with Δp is

$$\Delta E = \frac{(\Delta p)^2}{2m} \approx \frac{(6.2 \cdot 10^{-20} \frac{\text{g} \cdot \text{cm}}{\text{sec}})^2}{2 \cdot 1.67 \cdot 10^{-24} \text{g}} \approx 1.2 \cdot 10^{-15} \text{erg} \quad (5)$$

For comparison, the typical energy of the hydrogen bond (in water) is $1 \frac{\text{kcal}}{\text{mole}} \approx 7 \cdot 10^{-14} \text{erg}$ [4]. Thus, the difference between the quantum fluctuations energy and the typical energy of hydrogen bond is one order only, and this small contribution might be significant for the formation of fine molecular structures. Due to the quantum fluctuation contribution, the processing by any biological agent of a single nucleotide by means of formation of hydrogen bonds is less reliable than the simultaneous processing of a nucleotide complex. For a codon, the size of which is roughly 3 times larger than that of a nucleotide, the quantum fluctuation energy is one order less, and that provides a reliable transmission of information. In other

words, we can say that reading/writing of genetic information occurs by means quantum transitions of adiabatically isolated codon-anticodon pairs, i.e. in the quantum system of 6 nucleotides, three of those carry information content.

For complete analogy with quantum Bose gas, one could expect the codons with same nucleotide content (but different order of nucleotides) to code the same nucleic acid. The possible explanation for this does not happen is, that at early stages of the evolution this was really so, and each triplet was functioning as just a set of proto-nucleotides without any internal ordering, but later in course of the evolution with changing structure of nucleotides the symmetry with respect to permutation was spontaneously broken: the system evolved to a new ground state with less energy. What we observe now might be a result of this symmetry breaking. If so, this symmetry breaking should be non-degenerate: it maps 20 quantum states before the breaking to 20 states after it. It is important that if the proposed concept of adiabatically isolated quantum gas of nucleotides is valid, it guarantees exactly 20 possible states: not less, not more.

Aknowledgement

The authors are thankful to Dr. D. Chakalov for some bibliographical references related to this subject.
